INTRODUCTION

The gastrointestinal tract has developed a unique immunological system because of its close proximity to the intestinal contents. The system has evolved in such a way that it does not respond to the presence of beneficial microbes, but retains the ability to react quickly to the presence of harmful organisms. The challenge faced by the mucosal immune system is to generate an immune response of appropriate magnitude to control the microbial invasion while maintaining the integrity of the epithelial barrier. An imbalanced or improper immune response can result in a variety of inflammatory disorders of the gut.

In normal conditions human gut mucosa is infiltrated with a large number of mononuclear cells due to continuous stimulation by luminal antigens. This state of “physiological” inflammation is tightly controlled, as several mucosal cells interact to maintain an appropriate local immune response. Moreover, gut-associated lymphoid tissue (GALT) must constantly distinguish harmless antigens that are present in food and on commensal bacteria from pathogenic microbes.

For better understanding of the mucosal immune response it is useful to divide the gut-associated lymphoid tissue into inductive and effector sites, although recent data indicate that these distinctions are not absolute.

The inductive site for the mucosal immune response

The primary inductive sites are organized lymphoid aggregates placed in the wall of the small and large intestine. In the small bowel these aggregates are called Peyer’s patches and are composed of specialized follicle-associated epithelium, a subepithelial dome overlying B cell follicles that contain germinal centers, and interfollicular regions with high endothelial venules and effenter lymphatic vessels. Isolated lymphoid follicles are also present in high numbers in the wall of the large bowel and the appendix. Following ingestion, antigens and micro-organisms are transported from the gut lumen via specialized M cells, which are scattered among conventional epithelial cells overlying the dome of Peyer’s patch follicles. Compared with epithelial cells, with which they share a common progenitor cell, they have a pronounced capacity to transport a wide variety of substances and microbes to the subepithelial dome region. Here dendritic cells are the main antigen-presenting cells that bind bacterial products with their Toll-like receptors (TLRs). The latter are a part of the innate immune defense, recognizing conserved patterns on micro-organisms. Signals initiated by the interaction of Toll-like receptors with specific microbial patterns direct the subsequent inflammatory response. In the mouse model it has been shown that dendritic cells in different states of maturation exist at different sites of the Peyer’s patches. Dendritic cells in the subepithelial dome process antigen as relative immature cells and then migrate to the T cell region and present antigen to naive T cells. Here they have the properties of mature dendritic cells, with high surface expression of costimulatory molecules such as CD40, CD80, and CD86 and adhesion molecules such as CD44 and intercellular adhesion molecule (ICAM)-1. It is suggestive that the intestinal T cells with distinct regulatory abilities, such as those producing transforming growth factor (TGF) b and interleukin (IL)10, are stimulated by interaction with less differentiated dendritic cells in the Peyer’s patches. In the follicle such T cells provide help for the B cell switch to IgA, a process that is completed in the germinal center. IgA is the major mucosal immunoglobulin and can help to dispose of antigens without provoking the complement cascade. Following IgA switch and affinity maturation B cells migrate from the Peyer’s patches to the mesenteric lymph node via efferent lymphatic vessels and finally to the lamina propria where they undergo terminal differentiation into plasma cells.

The question arises about the signals that make a B cell home to the gut and specifically produce IgA. It has been shown that the vitamin A metabolite retinoic acid produced by GALT-derived dendritic cells confers gut tropism and, together with IL-6 or IL-5, induces IgA secretion. GALT-derived dendritic cells directly induce gut tropism in a retinoic-acid-dependent manner, and they induce class switching to IgA in B cells through a synergistic mechanism that also involves retinoic acid. This study is of clinical relevance as it might explain why vitamin A deficiency exacerbates diarrhoeal disease in malnourished children.

The effector site for the mucosal immune response:

The main effector site of intestinal immune responses is the lamina propria, where mature T and B cells migrate following induction in the Peyer’s patches. The lamina propria contains a large and heterogeneous group of lymphoid and myeloid cells; in addition to lymphocytes, there are macrophages, dendritic cells, neutrophils, and mast cells. Effector mechanisms that protect mucosal surfaces include cytotoxic T cells and effector CD4+ T cells for cytokine production and IgA response. Lamina propria T cells are mainly CD4+ T cells (60-70%), the majority of which express the ab T cell receptor (TCR; 95%) just as in peripheral blood. However, lamina propria T cells differ from peripheral blood lymphocytes in that they are in a more highly activated state and express CD25 and HLA-DR antigen, presumably as a result of continuous exposure to luminal antigens, but have a decreased proliferation rate when stimulated by mitogen or specific antigens. Another characteristic of lamina propria T cells is that they produce high levels of cytokines when stimulated with mitogen or via CD2. Lamina propria T cells have a mature or memory phenotype, indicated by the surface markers CD44hhi, CD62llo, CD45RBhi (mice)/CD45RO+ (human) and high levels of the integrin α4β7. Taken together, lamina propria CD4+ T cells are highly differentiated effector cells with a raised threshold of activation that prevents immune responses to harmless intraluminal antigens. CD8+ T cells account for about 30-40% of T cells in the lamina propria. This cell population contains cytolytic effector cells, which seem to control the level of viral infection and other micro-organisms that share an intracellular stage in their life cycle in the lamina propria. A more restricted T cell population develops independently of the Peyer’s patches and is integrated in the epithelial layer. These intraepithelial lymphocytes (IEL) are predominantly CD8+ T cells. In humans 5-30% of small intestinal IELs bear a gdTCR and lack CD4 and CD8 or are CD8+. Predominant CD8 expression implies that IELs react in a MHC I restricted manner to antigens. However, the composition of IEL is different according to the anatomical sites. While most human jejunal IEL are CD8+, there are much more CD4+ CD8- IEL in the ileum and large bowel, most probably due to the different intraluminal content of microflora and food. The CD8 molecule on IEL is expressed predominantly as a homodimer of the CD8a-chain. The phenotypic complexity of IEL therefore suggests that they have different functions. It has been demonstrated that CD4+CD8- and the CD4/CD8
double-positive IEL subset support the differentiation of Peyer’s patch B cells into immunoglobulin producing cells. Furthermore, surface expression of α,β, integrin, the ligand of which is E-cadherin on epithelial cells,16 and the production of keratinocyte growth factor by IEL17 suggest that some IEL populations play a role in maintenance of epithelial barrier integrity. In addition, TCRgdT cells may be involved in regulating the intestinal immune response.18 In the lamina propria IgA antibodies secreted by plasma cells keep the homeostasis of the epithelium by interacting with antigen within the gut lumen after epithelial transcytosis or inside infected epithelial cells or by formation of immune complexes with antigen in the lamina propria. However, it is clear that the antibody response is highly dependent on T cell help.19 This cell network in the mucosal immune system is highly integrated by the expression of specific costimulatory and adhesion molecules and the production of effector molecules such as cytokines.

Immune privilege in the gut:
The intestinal immune system constantly encounters foreign antigen, whether it be dietary antigen, components of the commensal gut flora, or antigens associated with pathogenic microbes. The gut falls squarely among those organs that can be considered immune privileged. There are two integral branches to immune privilege in the gut: oral tolerance and tolerance to commensal gut organisms.20

Oral tolerance
Oral tolerance is defined as the induction of a state of systemic immune nonresponsiveness to orally administered antigen upon subsequent antigen challenge. This mechanism presumably prevents the development of an immune reaction or allergy against intestinal intraaluminale antigens.

Most of data on oral tolerance have so far been obtained in the animal model of ovalbumin-TCR transgenic mice. T cells appear to be the major target of tolerance, and the reduction in antibody responses after antigen feeding are due to the reductions in helper activity rather than to a tolerization of B cells directly. The major mechanisms of tolerance induction are clonal deletion, clonal anergy, and the induction of suppressor cells.21 IL-12, a Th1-directing cytokine, may be a key regulatory cytokine for these various pathways in the mucosal immune response. Factors that suppress IL-12 production by antigen-presenting cells result in suppressor or regulatory T cells (Tregs) producing TGF-b and possibly IL-4 and IL-10, while factors that induce IL-12 production result in T cells producing the proinflammatory cytokine interferon (IFN) g.22-24 The nature and localization of the antigen-presenting cells responsible for tolerogenic presentation of fed antigens are unclear. T cell activation and/or deletion can be rapidly observed in the Peyer’s patches of antigen fed mice.25 Dendritic cells, which are the main antigen-presenting cells in the Peyer’s patches, are usually considered to have a high ability to activate T cells constitutively. However, there is increasing evidence that targeting antigen to resting dendritic cells, which lack costimulatory molecules, favors the induction of tolerance rather than immunity.26,27 In addition, enterocytes, which express Major Histocompatibility Complex class II molecules constitutively but lack costimulatory molecules such as ICAM-1,28,29 could also account for tolerogenic antigen presentation. Recent data indicate that Peyer’s patches alone are not important for the induction of oral tolerance. In a mouse model with targeted mutation in the gene of the tumor necrosis factor (TNF) a family the inhibition of the development of Peyer’s patches and mesenteric lymph nodes is associated with a loss of orally but not intraperitoneally induced peripheral immune tolerance.30

Commensal flora signaling and oral tolerance induction
As mentioned above, TLR signaling helps to communicate commensal microflora with the intestinal immune system and promote mucosal tolerance. Twelve TLR family members have been identified in mammals.31 The bacteria-responsive TLRs, TLR2, TLR4, TLR5, and TLR9, are among the most well studied TLRs; their ligands include bacterial lipoprotein/lipoteichoic acids, lipopolysaccharide (LPS), flagellin, and unmethylated bacterial and viral CpG DNA motifs, respectively.32 TLRs are expressed on a broad range of epithelial, endothelial, stromal, and hematopoietic cells, including immune cells such as macrophages, DCs, B cells, and some T cells.31,32 TLRs possess the so-called Toll/IL-1R homology (TIR) cytoplasmic signaling domains. When a microbial component engages a TLR, it dimerizes and recruits TIR-domain-containing adapter molecules to its TIR domain. These molecules include myeloid differentiation factor 88 (MyD88), TIR-domain-containing adapter protein/MyD88-adapter-like, TIR-domain-containing adapter-inducing interferon-b (TRIF), and TRIF-related adapter molecule.33 The specificity and diversity of cytokine production and other effector functions downstream of TLR signaling result largely from differential recruitment of these adapter molecules.31-33 For example, TLR4 has been shown to activate nuclear factor-kb (NF-kb) through the common MyD88 signaling pathway shared by all the TLRs except TLR3; however, TLR4 also uses a MyD88-independent TRIF signaling pathway, which has been shown to be critical for inducing costimulatory molecule expression in DCs and for optimal production at the messenger RNA level of the cytokines IL-12, IL-18, and IL-23.35 Many functions have been ascribed to TLR engagement in different cell types. TLR ligand binding has been shown to influence trafficking of intestinal lamina propria...
dendritic cells, to promote the generation of T-dependent, antigen-specific antibody responses by B cells, to moderate the expansion and suppressive function of Tregs, and to modulate the ability of DCs to display phagocytosed cargo in the context of major histocompatibility complex class II molecules. Since commensal microbes and pathogens possess complex combinations and subtypes of various TLR ligands, perhaps the combination of TLR signals induced by a particular microbe informs the immune cell whether a microbe is benign or not.

Microbes that colonize intestinal mucus have metabolic and transcriptional profiles that differ from their biofilm-independent counterparts. Perhaps this altered profile facilitates host/microbial cross talk at the intestinal epithelial surface, promoting host tolerance to these microbes. Individual commensal gut microbes have been shown to reduce the production of proinflammatory cytokines by intestinal epithelial cells (IECs) by modulating the location and activity of enterocytic transcription factors such as NF-kB. As the largest body surface to interact with the external environment, the intestinal epithelium (comprising IECs with tight junctions) serves as a barrier to unregulated transport and systemic dissemination of commensal and pathogenic microbes.

The physical epithelial barrier is reinforced with chemical components, including a glycocalyx formed by mucins bound to the apical surface of the IEC membrane and a sugar-rich mucus layer secreted by goblet cells of the intestinal epithelium. This mucus layer is capable of trapping those microbes that lack mucinases, adherence, colonization, or invasion factors and restricting their ability to access the IECs. Immunochemical members of the intestinal epithelial barrier include microbicidal peptides and proteins, such as defensins, and the recently identified intestinal angiogenins. Commensal microbes are actually capable of inducing host production of these anti-microbial peptides. Current evidence also suggests that the commensal flora can induce sIgA with low affinity but with broad specificity to facilitate the sequestration of gut microbes to the luminal side of the gut epithelium. The physical epithelial barrier is not absolute, however. Controlled transport of live microbes across the epithelial barrier is critical for the induction of adaptive immune effectors (B and T cells) with both protective and tolerant immune function.

Lamina propria dendritic cells have been shown to extend dendrites through the intestinal epithelium and into the lumen where they can sample antigen. IgA binding to commensal flora and luminal antigen facilitates adherence of these antigens to the M cells of Peyer’s patches and regulates transport of antigens across the epithelial barrier by M cells. Recently, enterocytes themselves have been shown to phagocytose enteric microbes both in vitro and in vivo, thus mediating controlled translocation of these microbes across the intestinal epithelium. It was demonstrated that intestinal epithelial cell lines expressing the innate immune receptor TLR4 were capable of phagocytosing the Gram negative bacterium E. coli in a TLR4-dependent fashion. Such cross talk between antigen-experienced epithelial cells and gut-resident immune effector cells may be critical to the maintenance of immune tolerance to luminal contents.

Commensals that cross the epithelial layer are phagocytosed by macrophages resident in the gastrointestinal mucosa. They are efficiently destroyed by superoxide and inducible nitric oxide generation among other biocidal mechanisms. Moreover, Smythies et al. have identified a population of human intestinal macrophages that neither express innate immune receptors, such as the lipopolysaccharide receptor CD14, nor produce proinflammatory cytokines, such as IL-1, IL-12, and TNF-a, in response to inflammatory microbial stimuli, in contrast to blood monocytes. Yet, while these intestinal macrophages exhibit ‘inflammatory anergy’, they are still fully capable of phagocytosis and bacteriocidal activity. These characteristics make this population of intestinal macrophages ideal subepithelial sentinels. They can destroy luminal microbes with systemic inflammatory potential before these microbes interface with the systemic immune system without eliciting inflammatory changes in the gut that would upset gut homeostasis.

The restriction of commensal-bacteria bearing dendritic cells to the mesentric lymph nodes can allow robust, local, protective mucosal immune responses to the gut flora (including sIgA production) in the absence of unneeded systemic immune responses. mesentric lymph nodes, thus, function as the center of immune privilege in the GALT.

**Tregs and tolerance to dietary and commensal antigens**

Immunoesquience to the gut commensal and dietary antigens is also facilitated by diverse immunoregulatory cells that actively suppress effector immune responses. Several different subsets of Tregs have been implicated in mucosal tolerance induction at the luminal/intestinal epithelial interface.

Intestinal epithelial and stromal-derived mediators promote the generation of immunoregulatory cells in the intestines; tryptophan-catabolizing enzyme indoleamine 2,3-dioxygenase (IDO)-mediated immunoregulation may be particularly relevant in the gut, as IECs constitutively express high levels of IDO. Newberry et al. demonstrated that non-bone marrow derived stromal cells in the intestinal lamina propria express basal levels of the enzyme cyclooxygenase 2 (COX2) and its arachidonic acid metabolite prostaglandin E2 (PGE2). As both COX2 and
PGE2 have been shown to prevent inflammatory responses to dietary antigens, this finding implicated intestinal production of COX2 and its arachidonic acid metabolite in the modulation of the immune response to luminal intestinal antigens. Other work has shown that enterocytes constitutively express thymic stromal lymphopoietin and preferentially induce ‘non-inflammatory’ dendritic cells, which secrete IL-10 and IL-6 and induce Th responses that support the production of barrier protective mucosal IgA. Smythies et al. have reported that cellular components of the intestinal stroma, namely lamina propria mast cells, secrete TGF-β capable of driving blood monocytes to take on the phenotype of normal intestinal macrophages, inflammatory anergy, coupled with potent phagocytic and bacteriocidal activity in the face of a plethora of immunostimulatory commensal bacteria.

### Immune privilege collapse in the gut:

#### Inflammatory bowel disease (IBD) and food allergy

In genetically predisposed individuals, breakdown in gut immune privilege can lead to disease at both ends of the Th1/Th2 spectrum, as shown in the figure below.

**Figure:** Immune privilege in the gut consists of tolerance to dietary antigens and to commensal microbes.

Food allergy, an adverse immune response to dietary proteins, affects 6–8% of children and 2–4% of adults and is characterized by gastrointestinal and extraintestinal symptoms and the production of large amounts of the Th2-dependent IgE. Other work has shown that enterocytes constitutively express thymic stromal lymphopoietin and preferentially induce ‘non-inflammatory’ dendritic cells, which secrete IL-10 and IL-6 and induce Th responses that support the production of barrier protective mucosal IgA. Smythies et al. have reported that cellular components of the intestinal stroma, namely lamina propria mast cells, secrete TGF-β capable of driving blood monocytes to take on the phenotype of normal intestinal macrophages, inflammatory anergy, coupled with potent phagocytic and bacteriocidal activity in the face of a plethora of immunostimulatory commensal bacteria.

While the absence of gut immune privilege to food results in food allergy, the consequences of immune privilege collapse to commensal gut flora is IBD. IBD comprises mainly ulcerative colitis (UC) and Crohn’s disease (CD) characterized by long term intestinal inflammation attributable to an exaggerated immune response. Earlier studies showed that in healthy humans, tolerance exists toward resident intestinal flora but is broken in active IBD. This finding was recapitulated in a mouse model of experimental colitis in which health was restored by treatment with the immunoregulatory cytokine IL-10 or antibodies to the proinflammatory cytokine IL-12. Ulcerative colitis (UC) is believed to encompass a heterogeneous group of diseases with different pathogenic mechanisms but common symptomatology. Patients with UC experience contiguous inflammation of their colonic LP. A spontaneously remitting and relapsing disorder, UC falls on the Th2 spectrum of intestinal disorders, as it is characterized by abnormally high amounts of the Th2 cytokines IL-4 and IL-13 produced by intestinal LP CD4+ T cells and natural killer (NK) T cells. The pathogenesis of UC is largely unknown, although animal models of UC appear to be driven by dysregulated immune responses to commensal microflora with subsequent generation of cross-reactive autoantibodies. Studies of Abreu et al. have implicated defects in TLR-mediated bacterial antigen sampling in the pathogenesis of the disease. Perhaps, a lack of microbially generated Tregs allows for inappropriate expansion of CD4+ Th2 and NK T-cell effector compartments, leading to excessive Th2 cytokine production and disease pathogenesis.

In contrast to UC, Crohn’s disease is a Th1-dominant IBD; in patients with Crohn’s disease, intestinal homeostasis is perturbed, and the production of inflammatory cytokines such as IFN-γ and TNF-α is increased in the lamina propria. The intestinal tract in Crohn’s disease is characterized by patchy transmural inflammation. Human studies suggest that primary defects in intestinal barrier function include altered mucus layer thickness and epithelial cell gene expression, leading to increased permeability of the intestinal epithelium. Increased intestinal permeability may facilitate barrier breach by commensal microbes and probable breakdown in systemic immunological ignorance to the commensal flora, contributing to disease pathogenesis. Lodes et al. found elevated anti-flagellin serum IgG levels in both Crohn’s disease patients and mouse models of IBD, supporting the conclusion that bacterial flagellins are the dominant antigen in humans with Crohn’s disease. Since TLR5 is only expressed on the basolateral surfaces of IECs, only microbes that have breached the epithelial layer can signal via TLR5, generating an active immune response to the protein. Defects in immunomodulatory mediator production by the intestinal epithelium of Crohn’s disease patients may also contribute to disease pathogenesis. Rimoldi

...
et al. reported that the immunomodulatory compound thymic stromal lymphopoietin was undetectable in epithelial cells from Crohn’s disease patients and that Crohn’s disease epithelial cells cannot induce ‘non-inflammatory dendritic cells generated by healthy human colonic epithelial cells. Defects in the CD8+ Treg compartment have also been implicated in disease pathogenesis. Future therapies for IBD may center on modulation of the gut luminal microflora in order to restore this Tregs compartment. To this end, Ince et al. have shown that colonization with helminth, which downregulates colitis in both human and animal models of IBD, upregulated the expression of TLR4 on lamina propria T cells, thus promoting the production of lipopolysachharide-induced TGF-β but not proinflammatory cytokines. In short, the addition of a helminth to an inflammatory intestinal environment may help restore the balance between commensal microbes and host, thus alleviating disease pathology.

**CONCLUSION**

The pathogens and harmless antigens from the bacterial flora and food constantly expose the mucosal surface of the gastrointestinal tract. The mucosal epithelial cells act not only as a physical barrier, but also as a local immune system, which plays a vital role in defense and self-tolerance. Dysregulation of this complex immune response can result in a collapse of immune privilege leading into chronic intestinal inflammation. Hence, the knowledge of the homeostatic regulation of the intestinal immune system paves the way for the development of the new immunomodulatory drugs in the therapy of IBD. Moreover, the generation of immune mediated cells through orally fed antigens could be the area of research in the treatment of certain autoimmune diseases.
