INTRODUCTION

Periapical lesions are the host response to endodontic infections caused by dental caries. Periapical lesions are abscess, granulomas or cysts. The cysts are of two categories: the bay cysts or pocket cysts and true cysts. Bay cysts are those in continuation with the root canal and true cysts are usually detached from the root canal.¹ These periapical cyst do not resolve with chemo mechanical preparation of the root canal alone. It should be combined with repeated long term intra canal dressing or surgical procedures. Large Periapical cysts managed with surgical therapy poses threat to adjacent normal tooth and their periodontium. Intra canal medication with Ca(OH)₂ and Iodoform (Metapex) is a novel method of treating periapical cysts.

PATIENTS AND METHODS

Patients with pain in the anterior teeth with clinical finding of trauma or carious lesions were subjected to radiographs. The differential diagnosis of these lesions is impossible without a histopathological examination. However radiological and clinical criteria for diagnosis of periapical cysts are presence of a non-vital tooth, presence of a radiolucency of >5mm, a well-defined radiolucency with a radiopaque border involving one or more tooth and the presence of straw colored fluid on aspiration or from the root canal.²

The periapical radiographs were carefully analyzed depending on the radiological criteria for diagnosis of
periapical cysts. Fifteen patients having all four criteria were taken up for the non-surgical management.

RC opened and straw colored fluid aspirated either from the root canal or from the cyst. Diagnosis of periapical cyst was confirmed. One precaution that was followed on aspiration of the fluid from the canal or from the cysts was the constant digital pressure over the cyst to avoid air entrapment. Diagnostic x-ray made (Figure-1). Length determined (Figure-2) and metapex paste placed in the root canal. Check x-ray showed extension of metapex paste into the cyst in five of our cases (Figure 3 and 4). The canal dressing changed every eight weeks and finally RCT completed after 6 months to one year depending on the size of the cysts and bone formation. The patients were followed up for the assessment of new bone formation in the lesion, period elapsed for healing, reduction in tooth mobility and reestablishment of periodontal ligament. Follow up radiographs, IOPA or occlusal view was taken every 3 months. At the end of six months (smaller cysts) or one and a half years (larger cysts), we found trabecular bone formation and resorption of extended paste in the cystic cavity (Figure 5). During the entire procedure no flare ups were seen. The healing of Periapical lesion is quite evident as the cystic cavity was being filled with bone.

**DISCUSSION**

Non-surgical management of these cysts should be adopted before advising surgery. The non-surgical treatments options are long term repeated intra canal dressing, aspiration and drainage through root canal, aspiration and decompression technique.

Repeated intra canal dressing is the most popular technique and we adopted intra canal dressing with Metapex paste. Metapex paste has calcium hydroxide, Iodoform, 38% (antibacterial), silicone oil vehicle and barium sulphate (radiopaque material). The non-water silicone oil vehicle promotes low solubility and slow diffusion of calcium hydroxide in the tissues.

The Periapical region has rich blood supply, lymphatic drainage and undifferentiated cells. The periapical cysts do not respond to conventional RCT alone. Most often after RCT patient develop persistent swelling, sinus tracts and recurrent infections. A non-vital tooth with a carious lesion leads to the formation of granulomas, Bay Cysts and true cysts. Bay Cysts have epithelium in continuation with the root canal system and true cysts develop as a self-perpetuating entity and do not respond to non-surgical management. Lin et al., suggested treatment of any periapical lesion with a conservative non-surgical management as a first priority. Microorganisms in the necrotic pulp release toxins into the periapical tissues at the interface between the apex and the periodontal tissues. The inflammatory process contributes to the formation
Devakumari, et al.: Conservative management of periapical cysts

The growth of the cyst is due to increase in hydrostatic pressure which enhances osteoclastic activity.

Since the introduction of Ca (OH)\(_2\) in 1920, it is the most popular and time tested intra canal medicament. It has a pH of 2.5 and diffuses into calcium and hydroxyl ions. This hydroxyl ion is an oxidant free radical and exerts microbicidal activity by disruption and damage to DNA, cell membrane, protein denaturation and nullifying the effect of bacterial endotoxins. The Oxidant free radical is also responsible for the inhibition of tooth resorption and tissue resolving ability.

Negri et al., claimed that intra canal medicaments can only be used as an adjuvant for cleaning and shaping and should not to be used as an alternative. The increase in hydrostatic pressure of the cyst leads to increase osteoclastic activity and aspiration and decompression of the cysts is of paramount importance in reducing this osteoclastic activity. Approximately 70% of cases with periapical lesions heal in two years of treatment. Increase in instrumentation 1mm beyond the apex leads to pressure release and strangulation of cyst. This leads to conversion of a cyst to granulomas and it gradually heals. A large peri radicular lesion may have a direct communication with the root canal system(apical pocket cyst) and responds favorably to nonsurgical treatment. Clinical studies have confirmed that simple nonsurgical treatment with proper infection control can promote healing of large lesions. When this treatment is not successful in resolving the periradicular pathosis, additional treatment options such as marsupialization or tube decompression should be considered.

In our institutional experience, we found that the large periapical cysts respond well to root canal therapy combined with repeated Metapex paste dressing. It is well documented worldwide that healing of those periapical lesions is excellent with this modality of treatment.

CONCLUSION

RCT combined with repeated intra canal dressing obviate the need for surgery in most of the similar clinical scenarios. Surgical treatment should be reserved for non-responding cases and in cases of true cysts in lieu of its complications.
