Abstract

Over-nutrition has presented itself as a significant public health issue in the past few decades. Its burden is increasing not only in developed countries, but also in developing countries. The objective of this review was to explore global and national burden of over-nutrition, its prevalence among children, and identification of the risk factors. It focused on assessing behavioral and socio-demographic attributes of parents that may influence obesity/overweight in children. For writing the literature review, national and international reports on over-nutrition, along with many journal articles on the related topic were reviewed. It showed that the burden of overweight/obesity has increased notably in the last three decades and is increasing more rapidly in developing countries. Moreover, it illustrated that its prevalence is high and has an increasing trend among children. Furthermore, the review also highlighted that parental attributes have an important influence on children’s nutritional status. Thus given the important role that parents play in the nutrition of children, parents need to be a focus of the strategies to control the growing problem of over-nutrition among children.

Key words: Child; Obesity; Overweight; Parents; Prevalence

INTRODUCTION

Nutritional status of individuals is an important marker of positive community health1. Malnutrition is a type of nutritional disorder with long lasting and serious consequences2, hence an important matter of public health concern. Although the word malnutrition is frequently used interchangeably with under-nutrition, in principle it also comprises of over-nutrition3. Under-nutrition encompasses a spectrum of disorders from underweight (low weight for age), to stunting (low height for age), wasting (low weight for height) and lacking in vitamins and minerals (micronutrient malnutrition)3. On the other hand, over-nutrition is defined as an abnormal or excessive fat accumulation that may impair health, and it includes both overweight and obesity4. In order to determine the occurrence and severity of these nutritional disorders, various indicators are used. Among them, anthropometric indices are most commonly utilized5. These include Body Mass Index (BMI), Mid Upper Arm Circumference (MUAC), weight for age, height for age, weight for height etc5.

For over-nourished children, the health outcomes are even worse than adults. It increases their chances of acquiring certain non-communicable diseases (NCDs) such as insulin resistance and heart disease early in life8. As overweight/obese children are likely to retain their status as adults8, they also have the possibility of getting many ailments when they are older. An estimated 44% of diabetes, 23% of ischemic heart disease, and 7 to
41% of cancer is attributed to be caused as a result of a being overweight or obese. Suffice to say that being an overweight child leads to major health issues as adults.

Considering the evidence of the rise of obesity, World Health Assembly (WHA) endorsed a Global Strategy for the Prevention and Control (GSPC) of NCD sin 2000. This commitment was strengthened further with the adoption of the strategy at the United Nation (UN) General Assembly on the Prevention and Control of NCDs in September 2011. Nepal showed its support by signing this declaration. It takes in account the fact that obesity is a multi-factorial disease, and has hence proposed a multi-sectoral strategy for its control and prevention. In Nepal, a Multi sectoral NCD Action Plan was developed in 2013. This plan aims to reduce preventable morbidity, avoidable disability and premature mortality due to NCDs in Nepal. It includes targets of halting the rise in obesity and diabetes, reducing the prevalence of physical inactivity and others that are directly or indirectly related to prevention of over-nutrition. Despite the plans to reduce the burden of over-nutrition, there is still an unintentional overlooking of the problem; with most of the government funds for improving nutritional status being utilized for prevention and control of under-nutrition. This has resulted in a slow decline in the number of undernourished children, but rising numbers of over-nourished population.

Prevention and control of over-nutrition is a difficult task because it is a multi-factorial disease and there are many variables that are incriminated as risk factors. These include socio-demographic factors, environmental factors, genetic factors and behavioral factors. Socio-demographic factors like educational level, income, occupation and employment status of parents; and behavioral factors like eating habits and physical activities, of both children and parents have been observed to play a major role in the nutritional status of children.

Even though over-nutrition is a preventable condition, lack of effective policies and inadequate implementation of the existing policies has led to slow progression of the attempt to prevent and reduce its burden. This may be due to lack of adequate clinical evidence addressing these issues. Many developing countries do not have adequate studies representing national level data. Also not all studies assess causal factors. This has caused a scarcity of adequate information about the occurrence of over-nutrition and associated risk factors. Even the identified risk factors are yet to be considered while developing strategies for its control.

This review aims to explore the global situation of malnutrition and it risks factors for over-nutrition with particular focus on parental attributes that affect occurrence of over-nutrition in the children. It intends to study about the knowledge gaps in these areas.

**BODY**

This narrative review focuses on the global and national burden of over-nutrition, its prevalence among children, and identification of causative factors, focusing mainly on parental attributes. Hence the literature review has been divided accordingly. For writing this review, national and international reports on over-nutrition, along with many journal articles on the related topic were reviewed.

**GLOBAL BURDEN OF OVER-NUTRITION**

Obesity has been on the rise for the past few decades, and it was declared as an epidemic by WHO in 1997. According to its estimation, the number of overweight people has increased by threefold since 1975. In 2008, about 1.4 billion adults were overweight globally; that number increased to more than 1.9 billion in 2016. The burden of over-nutrition among people has increased both in developed and developing countries.

According to the obesity update in 2017, the United States of America (USA) and Mexico were the top two countries with the highest percentage of obese people among OECD (Organization for Economic Co-operation and Development) countries in 2015. Similarly, in England, about a quarter of men and similar percentage of women aged 16 years and more were obese in 2016. Also, 40% and 30% of men and women respectively were found to be overweight in the same year. Likewise, the prevalence of obesity among adult Australian population in 2014-15 was 28%, which is almost one and half times rise from its value in 1995 (19%).

The epidemic of obesity, which started in affluent countries, has successfully penetrated world’s low income countries as well. In China, there was a substantial rise in the prevalence of overweight and obesity in adults between 2004 and 2010: increasing from 25-9% in 2004 to 32-3% in 2010. The problem has continued to grow and in 2015, China was ranked second in the world according to the prevalence of obesity among adults. Like China, the epidemic of over-nutrition has spread to South Asian countries as well. It was estimated that 20.7% of the women and 18.9% men in India were either obese or overweight in 2015 -almost double from the 2005 figures. Likewise, the Pakistani Demography and Health Survey (PDHS) 2012-2013.
estimated that a quarter of women of reproductive age group were overweight and about 15% of them were obese.

**PREVALENCE OF OVER-NUTRITION AMONG CHILDREN**

With the rise in obesity worldwide, its prevalence among children has been increasing as well. It was estimated that about 41 million children under the age of five and over 340 million children and adolescents aged 5-19 years were overweight or obese in 2016. In United States of America (USA), the prevalence of obese children aged 6-11 years increased from 7% in 1980 to almost 18% in 2012. Also, obesity was more prevalent among school-aged children and adolescents, when compared to preschool-aged children. Similarly, in the United Kingdom (UK), 16% of the children aged 2-15 years were obese while 12% were only overweight but not obese. In its neighboring country Denmark, the prevalence of children under 15 years of age who were either overweight or obese was 10%. Similarly, in the Australian continent, almost 1 in 4 children were either overweight or obese in 2014-2015.

The trends in malnutrition are changing, and now even developing countries have an increasing prevalence of overweight children. According to WHO, among all the children, approximately 52% and 20% were either overweight or obese and obese, respectively. The prevalence of over-nourished children has increased noticeably in the last 3 decades. The percent of overweight and obese boys increased from 0.74 and 0.03 in 1985 to 16.4 and 17.2, respectively in 2014. Similarly, among girls, the percent of overweight and obese population increased from 1.5 and 0.12 in 1985 to 13.9 and 9.1, respectively. In the study, children belonging to upper class family, advantaged ethnic group, having two or less siblings, or who had large weight at birth had a higher odds of being overweight/obese. In contrast, a study done in Kaski, Nepal among 838 school-going adolescents revealed lower prevalence of overweight (5.8%) and obesity (2.3%) among the children. Another study that was carried out among 15-19 year olds at four different places in Nepal (Lalitpur, Thimi, Kushadevi and Dhulikhel) reported that out of the 324 children, three percent were overweight and less than one percent of them were obese. The prevalence of childhood overweight and obesity was 52% and 20%, respectively.

Similarly, a cross-sectional study conducted among 501 students from high schools in Hyderabad city of Pakistan in 2009 illustrated that 12% of the students were obese and 8% were overweight.

**BURDEN OF OVER-NUTRITION IN NEPAL**

Based on BMI, WHO STEPS survey 2007 estimated that about 7.2% of the population in Nepal, was either obese or overweight and approximately 1.7% was obese in 2007. Similarly, WHO survey 2013 showed a rise in the numbers with about 17.7% of the population being overweight and four percent being obese. Similarly, according to last two Nepal Demographic and Health Surveys (NDHS), the number of over-nourished women in Nepal has risen. There was an increase in prevalence of overweight from 11% in the 2011 to 17% in the 2016. Likewise, the prevalence of obesity has also risen slightly from two percent to five percent in the same duration.

**PREVALENCE OF OVER-NUTRITION AMONG CHILDREN IN NEPAL**

In Nepal, research in the field of nutritional evaluation of children is mainly focused on assessment of under-nutrition. Nonetheless, several studies have been done in Nepal exploring over-nutrition as well. A study in private schools of Lalitpur, Nepal reported that 14.5% children were obese and about 11% were overweight. In the study, children belonging to upper class family, advantaged ethnic group, having two or less siblings, or who had large weight at birth had a higher odds of being overweight/obese. In contrast, a study done in Kaski, Nepal among 838 school-going adolescents revealed lower prevalence of overweight (5.8%) and obesity (2.3%) among the children. Another study that was carried out among 15-19 year olds at four different places in Nepal (Lalitpur, Thimi, Kushadevi and Dhulikhel) reported that out of the 324 children, three percent were overweight and less than one percent of them were obese. The prevalence of childhood overweight and obesity was 52% and 20%, respectively.
showed that prevalence of overweight was 4.1%. It also revealed that sedentary lifestyles of children and higher socio-economic status of the family was significantly related with overweight among children\(^6\).

While some of these studies have reported only prevalence of over-nutrition, others have assessed only socio-demographic risk factors associated with over-nutrition. But, none of them review other causal elements like parental feeding preferences for their children, children’s feeding habit, physical activity of children and their parents, etc., which have been implicated as important risk factors for over-nutrition. Additionally, most of the studies are done at local/sub national level, so the data is not nationally representative and cannot be generalized. Even the surveys done by WHO and Nepal government are focused mainly on children under 5 years of age or individuals above 15 years of age and they report only prevalence. Thus, there is a wide knowledge gap regarding the prevalence of overweight/obesity among Nepalese children and causes related to it.

RISK FACTORS FOR OVER-NUTRITION

Over-weight and obesity are varying points in the spectrum of over-nutrition; hence they have similar risk factors. Even though all the causal factors may have not been identified completely, some factors are considered to be contributing to over-nutrition in children\(^1\). There has been a very rapid change in the number of obese children within a relatively stable population so there is an indication that genetic factors may not be the primary cause for the alteration\(^4\). However, genetic factors, environmental factors, lifestyle factors, education level, economy, and physical activity - all have been shown to play a fundamental role in the pathogenesis of overweight/obesity\(^7\). Moreover, in case of children, not only their own factors, but associated parental factors seem to play an important role in determining their nutrition status\(^18\)–\(^35\).

Effect of education level of parents

Educational qualifications of the parents have been implicated as important risk factors that are inversely associated with obesity\(^6\). Higher the level of education of parents, there was lesser chance of off spring being overweight\(^4\). A study done in Lahore in 2005 illustrated that women’s education was a very important underlying factor responsible for the nutritional status of children from low socioeconomic class. Similarly, higher education of mothers was related to better nutritional status of children\(^4\).

Effect of employment status and occupation of parents

Employment of parents plays an important role in the nutritional status of children\(^18\)–\(^21\). Moreover, mothers’ employment status have a greater impact on children’s BMI than that of fathers\(^19\)–\(^21\). Additionally, not only employment status but other factors like duration of employment and whether both parents are employed at the same time, also effects BMI of children\(^18\)–\(^21\). Prevalence of overweight is also seen to vary with occupation of parents, over-nutrition being more common among children with parents who have non-professional rather than professional jobs\(^22\).

Effect of socio-economic status of parents

There is evidence that economic status of the family affects BMI of children\(^1\)–\(^4\). Those children who have parents with higher income have decreased risk of being overweight or obese\(^6\). Similarly, those children whose social status was low had three times more chance of being obese than children of the high social status\(^23\).

Effect of physical activity

Physical activity is another crucial element that decides whether or not a child becomes obese or overweight. In addition, physical activity and a person’s ability to perform physical activity are chief modifiers of mortality and morbidity related to overweight and obesity\(^6\).

A study of children aged 10 to 13 years illustrated that, a decrease in participation in sports was associated with increased BMI\(^3\)–\(^4\). Additionally, it was found that there was an inversely proportional relationship between moderate to vigorous physical activity and fat mass in 10 to 18 years old children\(^6\). Furthermore, lower BMI percentiles were seen in those children whose both parents were active\(^27\). Parent’s activity also encouraged their off-springs to participate in organized sports\(^27\). Even though adequate physical activity has been proven to have many health benefits along with helping controlling weight gain\(^6\), some studies have shown that they do not have significant effect on BMI\(^22\)–\(^25\),\(^28\).

Effect of feeding habits

Research has shown that eating habits and physical activity of an individual are strengthened early in life and are unlikely to change as they age\(^6\). So wrong habits formed during early childhood and adolescence may have a negative effect on nutritional status of individuals. This is supported by a study in China which concluded that high amount of fast food consumption by children and decreased physical activities among them are both very important factors for childhood obesity\(^4\).
Furthermore, it is widely known that parents influence children’s eating habit in many ways. Some parents make food choices for their children, while some act as role models for dietary preference, and yet other parents may use feeding practices to strengthen development of healthy eating patterns in their children. There are various theories about benefits and drawbacks of restrictions practiced by parents in feeding their children. Studies demonstrate that parental constraints on restricted food-items increase their child’s fondness for those foods, whilst forcing children to eat any food item was linked with reduction of preference for that food. Other studies have also shown associations between ‘controlling’ feeding strategies and childhood over-nutrition. Consequently, parents’ feeding strategies may have important influence on children’s eating patterns and weight. But, parental control and regulation of children’s eating habits may not always be counter productive and is likely to depend on how parents interact and communicate with their children on the topic. When children are encouraged to eat healthy foods, but also given some choices about eating options with parental explanation and rationales, higher intake of healthy food such as fruits and vegetables, and lower intake of energy-dense food can be achieved.

Effect of BMI of parents
Parental BMI has also been related to the BMI of children. Several studies in Europe have shown that there is a directly proportional relationship between children’s BMI and that of their parents. Furthermore, some studies suggest that this association may be due to both genetic and environmental factors. Studies also show that parents had limited ability to recognize that their child was overweight.

DISCUSSION AND CONCLUSION
This review aimed to assess the global and national burden of over-nutrition, its prevalence among children, and identification of the risk factors, with a focus on behavioral and socio-demographic attributes of parents that may influence obesity/overweight in children. This review showed that overweight/obesity is increasing rapidly in most countries around the world, and the burden is surprisingly higher in the developing countries. This epidemic is notably spreading among children as well. Moreover, researches show that parental attributes have an important influence on children’s nutritional status. However, the degree of influence may vary according to the different types of risk factors. Furthermore, as parents play an important role in the nutritional status of children, parents need to be one of the focus points while designing the strategies to control the growing problem of over-nutrition among children. Similarly, parents need to be educated about the importance of healthy eating habits and physical activities (of children as well as themselves) on the BMI of children and ultimately their health. Additionally, since children spend half of their time at school, the most feasible and effective approach to prevent over-nutrition would be to use preventive programs at schools.
