Abstract
Calcaneal apophysitis (Sever’s disease), is the most frequent cause of the heel pain in growing children. The diagnosis is generally made with a typical history and clinical examination. Imaging modalities including radiography and magnetic resonance imaging can help establish the diagnosis. In this case we report imaging findings of an 11-year-old boy diagnosed as Sever’s disease.

Introduction
Calcaneal apophysitis (Sever’s disease), is the most frequent cause of the heel pain in physically active growing children¹,²,³,⁴,⁵. The diagnosis of Sever’s disease is generally made with the typical history of posterior heel pain that exacerbates with physical activity and clinical examination findings of no or mild swelling without any local skin manifestations like erythema or edema¹,²,³. Although the requirement of using radiological methods for the diagnosis of Sever’s disease is controversial, foot radiographs are used to be obtained as a part of the routine clinical evaluation¹,⁴,⁵. Moreover, imaging methods could be useful in order to exclude other pathologies like fracture, tumors, and osteomyelitis⁶. However, radiography findings of this disease may be also seen as a variant of normal¹,⁴,⁵. Therefore, magnetic resonance imaging (MRI) can play a crucial role in the diagnosis of relevant cases⁶,⁷. We herein report an 11-year-old boy diagnosed as Sever’s disease with both radiography and MRI findings.

The Case
An 11-year-old boy was admitted to our hospital with the complaint of the right heel pain that exacerbates with the physical activity for the last two weeks. The pain initiated spontaneously without any history of trauma. There were no associated complaints or history of chronic illness. Physical examination was normal except tenderness of right heel. Laboratory tests were within normal limits as following: haemoglobin 13.8 g/dl, white cell count 5×10³/μl, platelet 300×10³/μl, erythrocyte sedimentation rate 16 mm/hr, C reactive protein 3.98 mg/dl. In the light of the clinical and laboratory findings, Sever’s disease was considered as a preliminary diagnosis due to presence of the isolated tenderness and heel pain on physical examination without any history of trauma and chronic illness, and accompanying unremarkable laboratory findings. Radiographs of the bilateral feet and magnetic resonance imaging (MRI) of the right foot were obtained to exclude other pathologies causing heel pain. Radiographs revealed increased density and fragmentation of calcaneal apophysis on both sides (Figure 1).

MRI showed findings of the right calcaneal apophysitis including: fragmentation, which was better seen on T1 weighted images, hyperintensity consistent with oedema on fat saturated T2 weighted images and enhancement following contrast administration on fat saturated T1 images (Figure 2).

The radiographs and MRI were otherwise unremarkable. Therefore, the diagnosis of Sever’s disease was established. He was recommended to restrict physical activities and prescribed oral anti-inflammatory drugs.

**Discussion**

Sever’s disease is thought to occur due to repetitive microtrauma caused by traction on the adhesion site of the Achilles tendon to the calcaneal tuberosity. This is the most frequent cause of the heel pain in children and the diagnosis is usually made with clinical history and physical examination. Patients often suffer from chronic heel pain and approximately in 60% of the cases complaints are associated with both heels. The average age at presentation is 11 years, ranging from 8 to 15 years. It is more commonly seen in boys with a 2:3:1, male:female ratio. Differential diagnosis list of the heel pain in a child may also include other conditions like fracture, osteomyelitis, Achilles tendinitis, retrocalcaneal bursitis, calcaneal cysts, tumors, and plantar fasciitis. During the clinical evaluation, foot radiographs are generally obtained for excluding other pathologies. Although fragmentation and increased density of the calcaneal apophysis observed in radiographs are defined as radiographic findings of Sever’s disease, these findings are not pathognomonic for the diagnosis and can be also seen in healthy children. MRI is another useful imaging modality which can be implemented in exclusion of other causes of heel pain particularly in doubtful cases. Inflammatory findings like bone marrow edema and enhancement after gadolinium administration within the calcaneal apophysis can be detected with MRI. Anti-inflammatory medications and restriction of physical activity are the treatment of choice in such cases.

**Conclusion**

In conclusion, Sever’s disease should be kept in mind in physically active growing children when the heel pain is present. In relevant cases implementation of MRI may help to establish the diagnosis.
