Abstract

Congenital Complete Heart Block (CHB) in a fetus is a rare diagnosis occurring 1 in 15,000 to 20,000 live births which can be diagnosed by echocardiography. It’s less talked disease. It is uncommonly reported even in countries where fetal echocardiography is performed in much higher numbers. For countries like Nepal, where small number of fetal echocardiography is performed, we present a case of lupus as the cause of congenital CHB.

Keywords: Congenital Heart Block, lupus, Echocardiography, Hydroxychloroquine

Background

Congenital Complete Heart Block (CHB) in a fetus is a rare diagnosis occurring 1 in 15,000 to 20,000 live births¹. CHB can be diagnosed by echocardiography alone². Fetal echocardiography is a boon for fetus to get such complex diagnosis in the womb. Getting the diagnosis early is important for the prognosis of the disease is poor³.

Case Report

A female of 27 weeks period of gestation was referred for fetal echocardiography. The anomaly scan had showed decreased fetal heart rate and renal dysplasia. The patient underwent fetal echocardiography. It showed cardiomegaly with cardiothoracic (CT) ratio > 0.6, decreased ejection fraction to 35% by eyeballing method and heart rate of 42bpm with regular rhythm from the doppler signal of aortic valve (Fig. no.1)

Figure 1: Doppler across aortic valve
M-mode was performed through right atrium and atrial rate of 153bpm was calculated. Diagnosis of Congenital CHB was made (Fig. no. 2)

With suspicion of lupus CHB, history and examination of mother was done and her blood was sent for investigation. It showed strongly positive for Anti SSA/Ro and Anti Ro- 52 (SSA) and positive for Anti SSB/La (Table:1)

Mother opted to discontinue her pregnancy for condition of the fetus explained. The risk of similar condition in next pregnancy was explained to the patient. She was advised for preconception gynaecologist consultation for next pregnancy. Repeated fetal echocardiography starting from early POG up to 28weeks POG was advised.

Discussion

Autoimmune related Congenital Heart Block is more common than non-immune related CHB affecting 2 out 100 fetuses exposed to maternal lupus antigen. All degrees of heart block can be diagnosed by echocardiography. M mode is taken through atria and ventricle and count the number of contractions of the two chambers. The contraction has to be regular and contraction of ventricle has to be slower than that of atrium to make the diagnosis of CHB. The other method is getting doppler signal through LVOT view to get the signal of aortic valve and mitral inflow at the same time. Doppler signal through mitral inflow having number of A wave dictates atrial rate and doppler signal through aorta denotes ventricular rate. The progression of 1st degree AV block to 3rd degree AV block can be avoided using hydroxychloroquine during pregnancy. Fetal echocardiography can help getting diagnosis during early phase and can guide through treatment to avoid such situation in forthcoming pregnancies. Having a greater number of cases, a proper guideline could be developed for frequency of fetal echocardiography for such cases. This will also help in developing management guideline in autoimmune CHB in fetus. Anomaly scan should be a routine for at least one time during pregnancy. A protocol to perform fetal echocardiography once radiologists report abnormality in regular anomaly scan can be made. Fetal echocardiography should be investigation in mind of gynaecologists to find cause of recurrent abortions.

Conclusion

One of the causes of recurrent abortion is lupus congenital CHB. Early detection can avoid the progression of degree of heart block and better outcome of fetus. Fetal echocardiography should be performed more frequently to uplift the standard of care for new life before leaving mother’s womb.

Disclaimers: Written consent was taken from the patient
