ABSTRACT

Background: The Staphylococci species are the predominant inhabitants of the nose and throat as normal flora, they are now becoming a threat due to their capacity to produce biofilm. Biofilm related infections are difficult to be treated unless it is diagnosed early. The aim was to study the prevalence of biofilm and beta-lactamase production in Staphylococcus isolates from nasal and throat mucosa in healthy volunteers.

Methods: Staphlococcal isolates were collected from nasal and throat swabs of 100 healthy volunteers at Gulf Medical University and Gulf Medical College Hospital, Ajman, UAE. Staphylococcus aureus or Coagulase Negative Staphylococcus (CoNS) was classified from growth on Mannitol Salt Agar and tube coagulase test. Biofilm production detected by Christensen’s tissue culture plate and Congo red agar methods. Beta-lactamase production among biofilm producers identified by iodometric tube method.

Results: Among 100 Staphylococcus isolates, 41 were Staphylococcus aureus of which 61% were biofilm producers of which 46.3% were beta-lactamase positive. Among the 59 CoNS isolates, 64.4% were biofilm producers of which 30.5% were beta-lactamase positive. Predominance of nasal Staphylococcal isolation observed among males at the age group of <20 years.

Conclusion: Biofilm-producing Staphylococcus inhabits the nasal and throat mucosa of healthy individuals. Beta-lactamase production was higher in Staphylococcus aureus positive for biofilm producers as compared to CoNS. Transmission of these biofilm producers with drug resistance factors from the healthy individuals to high risk patients with indwelling devices need to be considered.

Keywords: Beta-lactamase; biofilm; coagulase negative staphylococcus; staphylococcus aureus.
species (CoNS) is related to its capacity to produce biofilms. Such biofilm-related infections are extremely difficult to treat and have to be diagnosed early. The major components of the extracellular polymeric substance (EPS) of the Staphylococcal biofilm consist of poly-N-acetyl glucosamine (PNAG). Certain strains lack PNAG and among these strains the extracellular teichoic acid was noticed as a new component of Staphylococcal biofilm. Formation of biofilm in Staphylococcus is considered a four step process, consisting of adherence, accumulation, maturation and later dispersal. Biofilm is an important colonization factor as well as a virulence factor in bacterial adherence. Colonization occurs in the principal implants like central venous catheters, heart valves, ventricular assist devices, coronary stents, neurosurgical ventricular shunts, implantable neurological stimulators, fracture-fixation devices, arthro-prostheses, inflatable penile implants, breast implants, cochlear implants, intra ocular lenses and dental implants. The objective of this study was to determine the presence of biofilm formation and beta-lactamase production in Staphylococcus aureus and CoNS inhabiting as the normal flora in the anterior nares and throat of normal healthy individuals belonging to a Medical University.

Methods

The study was conducted among 100 healthy volunteers in Gulf Medical University (GMU), Ajman, UAE after getting the approval from the institutional Ethics Committee. Written consent was taken from all the volunteers after explaining the objective of the study and the procedure of taking samples. The nasal and throat swabs were aseptically collected and processed for Gram staining and isolation on Blood agar, Mannitol salt agar and Mac Conkey agar. The Staphylococcus isolates were categorized as Staphylococcus aureus and CoNS based on their cultural characteristics and standard tube coagulase test. Irrespective of age and gender, the CoNS isolates were significantly higher than Staphylococcus aureus in nasal and throat specimen (3:2). The number of Staphylococcus isolates was common among the younger age group (<20 years).

Results

Of the 100 nasal swabs collected 63 isolated Staphylococcus species, 24 were Gram positive bacilli (Diphtheroids) and 13 swabs had no growth. Out of 100 throat swabs 37 isolated Staphylococcus species, 2 Gram negative bacilli (Klebsiella pneumonia and Enterobacter sp.), 41 Gram negative cocci in groups (non- pathogenic Neisseria) and 20 swabs showed no growth. Staphylococcal isolation was 37% from the throat and higher in the nasal site (63%) of which 21% were Staphylococcus aureus. Isolation rate was higher in the age group below 20 years of age (58%), followed by the 21-30 years (26%). In the remaining age groups isolation was minimal. As shown in Table 1, Irrespective of age and gender, the CoNS isolates were significantly higher than Staphylococcus aureus in nasal and throat specimen (3:2). The number of Staphylococcus isolates was common among the younger age group (<20 years).

The presence of the biofilm formation was tested by two methods CRA and TCP methods and Beta-lactamase by ITM. Biofilm detection by both the methods were alike in Staphylococcus aureus (60.9%), whereas more positivity (64.4%) was obtained by the TCP method compared to the CRA method (57.6%) in the CoNS. Beta-lactamase was positive for Staphylococcus aureus (78%) and positive for CoNS (37.2%) as shown in the Table 2.

Figure 2. Biofilm production by Tissue Culture Plate method and Beta-lactamase production by Tube Iodometric Method in Staphylococcus isolates

Figure 2 shows the number of positive and negative results for biofilm production by both the tissue culture plate method and beta-lactamase production by Tube iodometric method among the Staphylococcus aureus and CoNS. Of the 100 Staphylococcus isolates 37 were negative for biofilm production and 46 were negative for beta-lactamase production. The beta-lactamase positive isolates were resistant to Penicillin and Ampicillin and susceptible to Vancomycin, Oxacillin and Rifampicin.

Discussion

Biofilm formation in bacteria is now a major problem in the medical field since it is responsible for many recalcitrant infections and also difficult to be eradicated. It contributes to virulence factors like the ability to avoid host immune response, restricted penetration of antimicrobial agents into the biofilm and exhibition of resistance to antibiotics due to various mechanisms including beta-lactamase production.

Staphylococcal isolation was high in the nasal site among the Japanese population, as reported by Tadayukiin.23 Our results were comparable, with increased Staphylococcus isolation (62%) from the nasal site. Karina et al. conducted a similar study among the medical students in Brazil and observed a percentage of nasal Staphylococcus aureus isolation of 40.8%.24 In our study the nasal Staphylococcus aureus isolation was 21%. Samie et al. conducted a similar study on biofilm and beta-lactamase detection using similar methods and detected 42% were biofilm producers among which 16% were beta-lactamase positive.25 In our study, 63% were biofilm producers among which 37% were beta-lactamase positive. Our study detected 63% of biofilm producing Staphylococcus isolates, similar to a study done in Pakistan (54.8%) by Joanna et al.26 The resemblance in the results may be due to similar culture, living conditions and geographical location. Both the conventional methods for biofilm detection (CRA and TCP) gave similar results in Staphylococcus aureus isolates, whereas the positivity in CoNS was slightly higher by the TCP method, agreeing with the earlier studies.27-28 However, Ruzicka et al. had done genetic studies detecting ica operon responsible for the biofilm production and compared with the similar conventional methods adopted in this study.28 The results had higher correlation with Christensen’s method than with the CRA method.27 Our findings differ from the earlier reports where the authors had suggested the CRA method to be superior to TCP.22,30,31

Colonization of biofilm forming CoNS is the current threat to effective antibiotic therapy because of the increasing difficulty in detection and management of infections, leading to fatal outcomes. All the beta-lactamase producers were resistant for Penicillin and Ampicillin but showed 100% sensitivity to Vancomycin corresponding with the earlier reports.24

There is a possibility of transmission of these virulence factors from the healthy individuals to those at high risk such as patients on long term catheterization, or having indwelling devices in a medical set up, which may be difficult to treat with the commonly available antimicrobial agents.
Conclusion

Biofilm detection is more reliable by the Tissue culture plate method than with the Congo Red Agar method. Also, the virulence factors, biofilm production and beta-lactamase production, seem to be present in the Staphylococcus isolates which normally inhabit the upper respiratory tract.

Since the biofilm and beta-lactamase virulence factors seem to be present in the normal flora of healthy individuals there is a need to screen for them among the healthy individuals who are posted at high risk units where medical device implantation, catheterization etc. are commonly carried out.
