This 40-year-old gentleman was referred to our institution following a road traffic accident 4 days prior to presentation. On examination, he had a Glasgow Coma Scale of 12/15 with no focal neurological deficits. There was no evidence of external injury. A noncontrast computed tomography (CT) scan of his head (Figure 1) was obtained emergently. It revealed widespread presence of intracranial air. Most notably air was present in the right frontal brain parenchyma, in both lateral ventricles and the third ventricle, and most of the subarachnoid spaces and cisterns (bilateral cerebellopontile angle cisterns, perimesencephalic cisterns, quadrigeminal cisterns, right sylvian fissure, and right cortical sulci). The patient was managed conservatively with high flow oxygen and head elevation, and subsequently developed hydrocephalus and underwent placement of a ventriculoperitoneal shunt. He was discharged from the hospital in 20 days in a stable condition.

It is not uncommon to have some degree of intracranial air following trauma especially when skull fracture involves the sphenoid and petrous bone.1,2 However, presence of such diffuse pneumocephalus (in the brain parenchyma, most of the subarachnoid cisterns and in the ventricles) in one patient is extremely rare. The most common location of intracranial air is the subarachnoid space.2 Presence of multiple air bubbles is associated with a bad prognosis.3 The air in our case was mostly likely sucked in from the frontal sinus through the fracture of the anterior cranial fossa.
