Abstract
Aim: To determine infective morbidity in post-operative cases of major Gynaecological and obstetrical surgeries.

Methods: This was prospective hospital based study carried out among patients who underwent major gynaecological and obstetrical surgeries at KMCTH. Patients with preexisting infection were not included in the study. This study was carried out over 2 month period from 1st December 2009 to 31st Jan 2010, where follow up ended on 4th February 2010. All patients had received antibiotics for 5 days postoperatively. The patients were followed up daily with 6 hourly temperature charting, daily physical examination, and urine routine/culture examination at removal of Foley catheter. The wound inspection was done on 3rd day of surgery.

Results: Total of 123 patients were enrolled in the study, of which, 73 (59%) cases were obstetrical and 50 (41%) cases were gynaecological, 4 (3.25%) patients had febrile morbidity, 2 in gynaecological and 2 in obstetrical cases. 1 (0.8%) patient of lower segment caesarean section (LSCS) had developed surgical site infection (SSI) which required resuturing of wound.

Conclusion: Commonest post operative infective morbidity following major gynaecological and obstetrical surgeries is febrile morbidity.

Keywords: Infective morbidity, febrile morbidity, surgical site infection

Introduction
Infection is the major complication during post operative period following major gynaecological and Obstetrical surgery, which is most often caused by over growth of the diverse bacterial flora. The bacteria invade the tissue and makes it vulnerable to infection due to placement of foreign body like suture, or catheter. Infection during post operative period may present with febrile illness. Fever may be due to infection of urinary tract, respiratory tract, wound infection and deep vein thrombosis occasionally, due to peritonitis.

Febrile morbidity during post operative period is defined as the rise of temperature ≥ 100.4°F (38 °C) after 24 hours of surgery and which should be recorded twice 4-6 hours apart1. The wound infection following elective gynaecological surgery varies from 2.1 to 3.5 %1. Likewise, Urinary Tract Infection becomes the major post operative infection following vaginal surgery2. The risk of bacteriuria develops in approximately 1-2% following catheterization3. In very few cases, pelvic abscess and peritonitis may complicate the post operative process of surgery. Fortunately, use of prophylactic antibiotic in surgery reduces the frequency and severity of infective complication. This study was carried out to determine post operative infective morbidity like febrile morbidity, urinary tract infection, wound infection and chest infection in patients who underwent gynaecological and Obstetrical Surgery.

Methods
This is a prospective analytical study. It was conducted at obs/gyn department of Kathmandu Medical College

Teaching Hospital over the period of 2 month, from 1st December 2009 to 31st January 2010 while, follow-up of cases were completed on 4th February 2010. The Patients who underwent major gynaecological and obstetrical surgeries were included in the study. The patients with infection like fever, abnormal urine reports, or who were on antibiotics before surgery were excluded from the study.

Total of 123 patients were included in the study. All of them had received antibiotic prophylactic for 5 days post operatively. They had indwelling catheter for 24 to 48 hours after surgery.

The patients were evaluated daily after surgery, until the day of discharge; to investigate development of any complication. The patients were evaluated every day for fever and chest infection. Daily 6 hourly temperatures were recorded with standard mercury thermometer.

Chest infection was suspected in patients with chest pain and cough. All patients were evaluated in detail so as not to miss any signs of chest infection. The patients with suspected chest infection were further evaluated with chest X-ray. Urine routine examination and culture were sent for every patient after removal of Foley catheter and reports were evaluated for urinary tract infection.

Surgical wound site inspection was done on 3rd day of surgery. Wound indurations, discharge from wound, wound gaping were considered as surgical site infection (SSI). Patients with discharge from wound and wound gaping were further evaluated with wound swab culture.

Results
During the period of 2 months 123 patients were included in the study that underwent major gynaecological and obstetric surgeries. Of the total cases 73 cases (59%) were Obstetrical cases and 50 cases (41%) were gynaecological cases. Among 73 Obstetrical surgery 20.5% were elective and rest were emergency. Similarly among the gynaecological surgery 90% were elective.

Out of 123 patients 4 (3.2%) had febrile morbidity, of which 2 were in gynaecological surgery and 2 were in obstetrical surgery. Urinary Tract Infection was seen in 1 case of gynaecological surgery, but it was not seen in obstetrical cases. Only 1 case of wound infection was found in obstetrical surgery. No case of chest infection had occurred during study period. Overall infective morbidity was found in 6 cases (4.9 %). Fever was not seen in cases with Urinary Tract Infection and wound infection.

Discussion
Overall infective morbidity during post operative period was seen in 4.9 % (6/123) cases of surgeries. Wound infection was seen in 1(< 1%) case of elective caesarean section which required secondary resuturing. Staphylococcus aureus was grown in that wound. Reports from the various centers had shown up to 10 % of cases wound infection.

Saha et al had studied 50 cases of hysterectomy at KMCTH. She found 6% wound infection in her study but compared to her wound infection was very less in our study (< 1%). Wound infection after hysterectomy was reported 8.6% by Taylor. Consulo studied 88 wound swab culture from abdominal hysterectomy, he reported 61.3% culture positive cases but no cases of wound infection was found in abdominal hysterectomy in our study. In Spain Ecoli, Staphylocococcus aureus and Mycoplasma hominis were common pathogens for wound infection following hysterectomy.

Urinary bacteria growth was seen only in 1 (<1%) case of gynaecological surgery. Routine urinary examination showed abnormal finding in another 3 cases but bacterial growth did not occur in those cases. Ojha from TUTH had reported higher incidence of Urinary Tract Infection. She had analyzed 316 gynaecological and Obstetrical case records for bacterial growth in urine according to duration of catheterization. She reported 46 % positive urinary bacterial growth in both gynaecological and Obstetrical surgery. Similar Incidence of urinary tract infection (40%) was reported by Kingdom.
Febrile morbidity was seen only in 3.2% cases in our study. It was reported higher in studies from Netherland and Wales (6.5%-12.5%) but study from KMCTH reported only 2% febrile morbidity following hysterectomy.5,10

**Conclusion**

To conclude infective morbidity, including febrile morbidity, UTI and wound infection is very less following gynaecological and obstetrical surgeries irrespective of elective or emergency surgery. Febrile morbidity is commonly encountered morbidity during post operative period.
