ABSTRACT

Urinary bladder diverticulum presenting as an inguinal hernia is an uncommon condition found in about 1-5% of inguinal hernias. Long standing increase of the intravesical pressure resulting from urinary bladder outlet obstruction can cause both secondary bladder diverticula and groin hernias. We present a case of urinary bladder diverticulum herniating through the left inguinal canal, which was confirmed by micturating cystourethrogram. Although these conditions are usually diagnosed intraoperatively, radiological diagnosis still holds its utmost importance to improve the overall management.

Keywords: Bladder diverticulum; Cystography; Hernia, inguinal

INTRODUCTION

Inguinal bladder is an uncommon condition found in 1-5% of inguinal hernias (IH). It can be due to long standing increase of the intravesical pressure which gives rise to secondary bladder diverticulum and hernia. The commonest cause of rise of intravesical pressure is bladder outlet obstruction. In males, most common cause for bladder outlet obstruction (BOO) is benign prostatic hyperplasia (BPH). A careful clinical suspicion and judicial radiological assessment is a must for proper diagnosis of inguinal bladder hernia.

urinary tract symptoms (LUTS) and left inguinal swelling. He was diagnosed BPH with inguinal hernia clinically and was asked for micturating cystourethrogram / retrograde urethrogram (MCU/RGU) for further evaluation.

CASE REPORT

A 63 year old male presented to Department of Urosurgery outpatient department (OPD) with chief complaints of left inguinal swelling and difficulties in micturition including incomplete voiding. The swelling would reduce when compressed with increased urinary flow. During clinical examination, there was a painless irreducible swelling seen in left inguinal region with measuring around 7x5 cms. On ultrasound, prostate gland was enlarged in size (63.0 gms) with left inguinal hernia. Micturating cystourethrogram demonstrated small globular outpouching of the left lateral wall of the urinary bladder. On further instillation of the contrast, the contrast filled outpouching was found to herniate into the left inguinal region (Fig 1, Fig 2). The diverticulum was decreased on size with passage of urine and finally collapsed on external pressurized emptying with no obvious reflux of contrast into ureter. Urinary bladder demonstrated minimal trabeculations.

DISCUSSION

Herniation of the urinary bladder is a relatively uncommon but not a rare condition.\(^1\) It occurs when the urinary bladder or ureter herniates into the inguinal canal. Herniation can reach to scrotal sac or sometimes through femoral canal, which is even very rare. Bladder herniation occurs in an acquired direct inguinal hernia with the bladder pulled into the hernia, together with a sheath of peritoneum, which forms a sac like structure. Some factors are associated with the pathophysiology of bladder herniation, such as chronic urinary obstruction, obesity, elderly population, decreased bladder tone, and weakness of the pelvic musculature.\(^4\) These hernias have a predilection for the right side.\(^5\) Different diagnostic modalities may be used. Ultrasound (US) is first, cost effective and most accessible diagnostic modality. It may demonstrate hypoechogenic mass lesion protruding from the bladder through the inguinal canal into scrotum.\(^6\) Voiding cystourethrography is best diagnostic imaging modality for inguinal bladder hernia. It may reveal dog-ear shaped bladder in the scrotum. Indirect signs are small asymmetric bladder, incomplete visualization of bladder base and lateral displacement of the lower ureter. In typical supine radiographs, they are usually missed. Prone position can improve the

detection, while erect radiographs can detect 100% of such hernias. Pointing of the bladder toward the side of the hernia, i.e. angulation of the bladder base anteroinferiorly, is the CT sign of bladder herniation. Findings in MRI are similar to CT features of bladder hernia, however coronal and sagittal planes can give better vascular outline. Also, relations to adjacent vascular landmarks can be well identified.

CONCLUSION

Inguinal bladder hernia should be considered in an old male patient presenting with lower urinary tract symptoms and inguinal swelling. Imaging has pivotal role in the diagnosis as well as overall management of these cases.
